Let  $n \in \mathbb{Z}^+$  and  $m \neq n \in \mathbb{Z}^+$

Let  $C_n$  be the Elias Omega codeword for  $n$  and  $C_m$  be the encoded Elias Omega codeword for  $m$ .

$C_n$  and  $C_m$  are composed of a length encoding and a data encoding component.

Let  $L_n$  be the length component of  $C_n$  and  $L_m$  be the length component of  $C_m$ .

Let  $D_n$  be the data component of  $C_n$  and  $D_m$  be the data component  $C_m$ .

Let us assume  $C_m$  and  $C_n$  are Elias Omega codewords,  $|C_m| > |C_n|$  and  $C_n$  is a prefix of  $C_m$ . Hence,  $C_m$  can be rewritten as  $C_n x$  where  $x$  is a string of bits.

Let us now consider the decoding of  $C_n x$  ( $C_m$ ).

Given the structure of Elias Omega encoding, the length segment  $L_n$  is composed of one or more recursive encodings of the next code segment length minus 1. These length segments have had their most significant bits flipped to be 0 instead of 1. Additionally, the data component  $D_n$  encodes the actual integer value of  $n$  in binary and starts with a 1, distinguishing it from the length components in  $L_n$ .

Given  $C_n$  is an Elias Omega codeword, we decode the length segments by using the current known length segments until we reach a component which has a 1 in the most significant bit indicating we have reached a data component.

Assuming  $|C_n| < |C_m|$ ,  $L_n < L_m$  because the length of Elias Omega codewords depends on the number of bits used to represent the positive integer. Therefore, as we decode, we will encounter  $D_n$  before  $D_m$  as  $L_n$  dictates how we decode the codeword. As a result, the decoder will output  $D_n$  instead of  $D_m$ , which was our intended target.

Therefore,  $C_m$  cannot be a valid Elias Omega encoding, thus contradicting our assumptions. Hence, our assumption that there exists two Elias Omega codewords where one is a prefix of another, is false. Finally, we can conclude that Elias Omega encoding is prefix-free.
